

Organic Peach Production in Florida¹

David Campbell, Danielle Treadwell, Ali Sarkhosh, Oscar E. Liburd, and Jeff Brecht²

Introduction

Peach cobbler, peach ice cream, and ripe peaches picked from the tree are some of the ways that we enjoy peaches. Organic peach acreage in the United States increased more than any other type of organic fruit between 2008 and 2011, but that increase occurred west of the Rocky Mountains (Perez and Plattner 2013). In 2019, organic peaches were produced on 238 farms representing over 3,237 acres. These farms, primarily located in California, Washington, Colorado, and Oregon, grew 20,208 tons of peaches worth over \$36 million (USDA NASS 2020). In the southeastern United States, the majority of peach production occurs in South Carolina (17,566 acres) and Georgia (11,877 acres), but only three farms in these states were certified organic (organic certified acreage data not published; USDA NASS 2020).

Approximately 2,000 acres of peaches are grown in Florida, mostly in Martin, St. Lucie, and Polk Counties, but only four farms (24 acres) are USDA organic certified (USDA NASS 2020). The combination of increased consumer demand for organic products and limited organic peach production in the Southeast may indicate that market opportunities exist for expanded organic production in Florida. In general, organic farmers in Florida are optimistic, and results from a recent survey of all USDA-certified

organic farms in Florida revealed that 30% of the operations planned to increase production, while only 4% planned to discontinue production (USDA NASS 2020). Organic peach production in Florida can be accomplished with proper management, including cultivar selection, pruning, thinning, fertilization, irrigation, integrated pest management, harvesting, and postharvest handling (Figure 1).

This publication is designed for small- and mid-size farm operators who are certified organic or who desire to use organic practices, and for producers selling fruit directly to consumers. This fact sheet includes recommendations for best practices and references for different types of inputs. This document also references other UF/IFAS Extension EDIS publications that may mention conventional inputs that would be prohibited in organic systems; please verify compliance with your certification agency before using any inputs on your farm.

Andra Johnson, dean for UF/IFAS Extension.

Market Opportunities

The first domestically grown peaches are harvested as early as March in south-central Florida. In May peaches become available from Georgia, South Carolina, and California, with peak domestic production in June–August (Figure 2). In 2019, the farm-gate price for all peaches sold in May was worth 46% more than for peaches sold in June (USDA ERS 2019). In Florida, the combination of a price-premium for both early and organic fruit is offset by small fruit size as compared to the industry standard minimum 2.5 inches (6.4 cm) in diameter (Figure 3). Due to small fruit size and limited production, most Florida-grown organic peaches are sold from farm stands and pick-your-own (U-Pick) operations.

Growers selling directly to the public may utilize roadside stands, farmers' markets, or community-supported agriculture models. Growers could also attract customers directly to the farm through U-Pick operations or agritainment, including agrotourism and farm entertainment. For more information on the organic industry in Florida and these other direct-to-consumer sales activities, visit the EDIS publications FE732, *Economics of the Organic Food Industry in Florida* (<https://edis.ifas.ufl.edu/fe732>), RM008, *Agritainment: A Viable Option for Florida Producers* (<https://edis.ifas.ufl.edu/rm008>), and AEC623, *Florida's Agritourism Laws* (<https://edis.ifas.ufl.edu/wc285>).

Figure 2. Total and southeastern (SE) US peach production (Florida, Georgia, and South Carolina) and imports (USDA ERS and NASS 2020). Monthly values are estimated based on production schedules and the area under the curve represents total yield.

Production Planting Stock

If you are a producer starting a new orchard or if you plan to transition some conventional acreage to organic, keep in mind that your soil and nursery stock must be managed using approved methods. Maintain the following thinking as you develop your organic system plan: the **system** is

certified; the **inputs** are compliant or approved for use in that system; and the **crop** bears the organic label.

Whether the land is owned or leased, producers seeking certification should be ready to provide 3 years of field management records to their certification agency. Complete and accurate records are necessary, even if the field hasn't been planted to a crop. The land must not have received prohibited substances for a minimum of three years before the expected harvest date in order for the land to be eligible for certification. Although more common for blueberry (Phillips et al. 2020), some producers may grow peach trees in pots that are arranged on landscape fabric or under a protective structure. In a 2019 policy memo, the USDA NOP deputy administrator clarified that land used for container systems as well as the container system itself must meet the NOP requirements (Tucker 2019). In other words, the growing medium, stock plants, inputs, as well as *the soil under the pots* must meet the standards for certification to sell the fruit with a certified organic label. This rule was added to ensure organic integrity.

As of 2020, all commercially available cultivars in Florida are grafted on the 'Flordaguard' rootstock (Sherman et al. 1991), which provides resistance to the endemic root-knot nematode, *Meloidogyne floridensis* (Handoo et al. 2004), and is productive in Florida's limited chill hour conditions. Peach cultivars are planted on other rootstocks that are suitable for different regions and growers are encouraged to confirm the scion-rootstock combination before purchase. Peach trees have an estimated life span of 10–15 years, and it is recommended that growers include replanting strategies in their organic systems plan. For example, if trees are purchased from conventional nurseries, certified organic growers will need to wait at least 12 months before marketing the fruit as organic even if the tree bears fruit before the end of the required waiting period (Table 1). Your local UF/IFAS Extension agent will be able to assist you with locating nurseries in your area (<https://sfyl.ifas.ufl.edu/find-your-local-office/>).

Trees from nurseries are generally not pruned but should be pruned during the next dormant season (see training and pruning section below and EDIS publication HS1111, *Training and Pruning Florida Peaches, Nectarines, and Plums* [<https://edis.ifas.ufl.edu/hs365>] for more information). Trees to be planted in the fall should be approximately 2.5 to 4 feet (76 to 122 cm) tall, be generally healthy with green leaves, and have no damage or visible gum on the trunk (see insect pest and pathogen management section below). Between 117 and 290 trees can be planted per acre with 10 to 15 feet (3 to 4.5 meters) between trees (within

row) that are grown in rows that are 15 to 25 feet (4.5 to 7.6 meters) apart (between rows). For more information on production practices, visit the EDIS publication RFAC018, *Opportunities for Small Farms: Peach and Nectarine Production Review* (<https://edis.ifas.ufl.edu/mg374>).

Chill Requirements

Peach is a temperate-zone, deciduous fruit tree that requires cold temperatures (chill hours) during dormancy for optimum growth and fruit set. The minimum chill hours required for optimal fruit set are cultivar-specific and known as the chill unit requirement. Before breeding efforts from researchers at the University of Florida in the 1950s, most peach cultivars required approximately 650+ chill units, but now growers have the option for low-chill cultivars with requirements as low as 100 chill units (which permits peach production in central Florida). Chill units can be calculated by several models, but the model that defines a chill unit as 1 hour between 32°F to 45°F (0°C to 7°C) is appropriate for low-chill cultivars (Richardson et al. 1974; Sharpe et al. 1990). Florida growers can determine local chill unit accumulation data from the Florida Automated Weather Network (<http://fawn.ifas.ufl.edu/>) or the AgroClimate website (<http://agroclimate.org/>) and should select a cultivar suitable for their location. Peach trees will survive if the chill unit requirements are not met, but the tree may not bear fruit, may have an uneven bloom, and may have fruit with growth defects such as a bulging suture. For more information on cultivars, the chilling requirements, chilling unit map, marketing, labor, and planting guidelines, visit the EDIS publication RFAC018, *Alternative Opportunities for Small Farms: Peach and Nectarine Production Review* (<https://edis.ifas.ufl.edu/ac018>).

Beyond meeting the winter chill requirements, early ripening is also a critical trait for Florida production. The number of days from flowering to fruit set, or the fruit development period, is shorter for low-chill cultivars such as ‘Flordadawn’ that produces fruit in as little as 60 days after flowering. The most popular cultivars currently in production, ‘UFBest’, ‘TropicBeauty’, ‘UFSun’, and ‘UFOne’, have respective chill unit requirements of 100, 150, 100, and 150 hours and fruit respective development periods of 85, 89, 90, and 95 days. The UF/IFAS peach breeding program in the Horticultural Sciences Department is actively developing improved peach cultivars for Florida. For more information on available cultivars, visit the EDIS publication Cir1159, *Florida Peach and Nectarine Varieties* (<https://edis.ifas.ufl.edu/mg374>). Breeding within organic systems may produce cultivars with traits better suited for organic production, but the most important trait for all systems is chill hours.

Establishment

Site identification and preparation are also important to maximize tree and fruit growth. UF/IFAS Extension encourages all growers to submit a soil sample to a licensed soil laboratory prior to initially planting and yearly thereafter. Visit the Extension Soil Testing Laboratory’s (ESTL) website (http://soilslab.ifas.ufl.edu/ESTL_Home.asp) or check with your county Extension office for more information about how to collect and submit a soil, manure, or compost sample, and to obtain additional guidance about fertility management. Optimum soil nutrient levels for conventional and organic peach trees grown in Florida are still being developed.

Although peach leaves only need 50% of the intensity of full sun for maximum photosynthesis, planting in full sun is still recommended to account for cloud cover and to reduce leaf wetness. Plant trees in well-drained soils because most rootstocks are not tolerant to flooding and a higher density of trees can be planted on lighter soils. If possible, plant at higher elevations because flowers and growing fruits can be damaged by early-season freezes when colder air settles at lower elevations. Even at higher elevations, overhead irrigation that waters the entire tree during early-season freezes may be needed to avoid crop loss. For more information about specific weather conditions that will determine whether irrigation will be helpful or harmful to young fruit during cold weather, visit EDIS publication ABE 372, *Using Psychrometric Chart for Frost Protection* (<https://edis.ifas.ufl.edu/ae406>).

Trees can be transplanted at any time of the year. Transplants grown in pots are best planted after the last freeze in the spring, and bare-root transplants are best planted in the fall or winter. Trees should be placed in the ground, without stakes, such that the ground soil line is even or slightly above the media in the transplant pot or former soil line for bare-root trees. Holes should be twice as wide as the pot and can be amended with finished compost that is mixed with native soil prior to planting. Peach trees have been grown in large pots (such as a 5 gallon [640 fl oz] or larger pot) for experiments and where in-ground planting is not possible, but recommendations and production estimates for pot production have not been determined.

Sanitation Training, Pruning, and Thinning

Growers should clean tools to remove surface dirt and plant residues, and then sanitize with approved products before tree training and pruning to reduce the risk of spreading pathogens. Although rinsing with a sanitizer is not required for tools used exclusively in certified systems, growers opting to use one are required to follow dilution instructions on the product label. A chlorine-based sanitizer is the most commonly used sanitizer for nonfood contact surfaces, such as hand tools and trimming equipment. Some bleach products have surfactants or fragrances that are not allowed in organic production. See the [NOP Handbook Section A. Standards 5026](#) and [e-CFR § 205.601](#) for more information on approved sanitizers. More information on postharvest fruit sanitation is provided in the Harvest and Storage section below.

Most peach trees in the Southeast are trained so the overall shape resembles an open vase with the trunk and limbs resembling the stem and cup of a standard wine glass, respectively. Training involves cutting limbs on young trees to promote the development of three to six strong scaffold branches that are above and close to the rootstock/scion junction (2 ft or 61 cm above the ground). Branches extending from the rootstock itself should be removed and can easily be identified by their red leaves as opposed to the green leaves of the scion's branches. Secondary and tertiary branches will grow off the scaffold branch and *new flowers/fruit will develop on wood that grew in the previous year*. After one to two years of pruning to develop the overall shape, yearly pruning is required.

In contrast to citrus, peach trees grown in Florida require two pruning events, one in the summer and one in the winter. Summer pruning occurs after harvest (postharvest pruning) in May and no later than June, and the main purpose is to maintain a reasonable height for the next harvest season with sufficient width to allow machinery to pass without damaging limbs. For more information about summer pruning, including pictures, visit EDIS publication HS1377, *Summer Pruning in Low-Chill Peaches Grown in Florida* (<https://edis.ifas.ufl.edu/hs1377>). Winter pruning occurs after the trees have entered dormancy (leaves have fallen) and occurs around December. The purpose of winter pruning is to remove dead wood, limbs growing straight up from the center of the tree (also called water sprouts), and other twigs that may bear leaves that impede air flow or damage growing fruit. For more information on pruning, including pictures, visit EDIS publication HS1111, *Training and Pruning Florida Peaches, Nectarines, and Plums* (<https://>

edis.ifas.ufl.edu/hs365). After the last chance of a freeze, but before the peach fruit begin to rapidly increase in size, flowers and fruitlets should be removed by hand or with machinery (also called thinning) to a density of one fruit for every 6–8 inches (15–20 cm). To promote maximum fruit size, fruitlets and flowers should be thinned when the fruitlets are no longer than 1 inch (25 mm) from stem to tip and their stones are still soft (Figure 3). However, thinning later, after the stones harden and the fruit are longer than 1 inch, will not increase final fruit size. For more information about fruit thinning, including pictures, visit EDIS publication HS1324, *Thinning Florida Peaches for Larger Fruit* (<https://edis.ifas.ufl.edu/hs1324>).

Figure 3. (A) Approximate maximum size of peach fruitlet (1 inch or 2.5 cm) for thinning (note the ruler in the image is in cm and begins at 10 cm). Thinning should be done before fruitlets reach this size, but it is recommended to do so after the risk of cold damage has passed. (B) Peach in a standard sizing ring that shows the size of this fruit has a diameter greater than 2.5 in. Most harvested peaches in Florida are smaller than this size.

Orchard Floor and Weed Management

Commercial orchards are planted in parallel rows, and the ground of the orchard can be divided into two sections, the area directly under the canopy (row middle) and between the trees (row alley). Row alleys typically consist of existing vegetation that is regularly mowed, while row middles are kept vegetation-free. Incorporation of cover crops in the row middle or row alley could improve soil health, but more information is needed regarding species selection and management to increase nutrient availability, reduce competition, and increase the number of beneficial insects while maintaining insect pests below acceptable levels. Maintaining vegetation, different tillage practices, and growing cover crops in the row middle and/or row alley have had positive (Reeve et al. 2013), negative (Antonelli et al. 1998), and insignificant (Belding et al. 2004) effects on peach trunk growth. Reducing peach tree competition for resources (water and fertility) with other plant species in the row middle when trees are first established is important for long-term orchard productivity. Row middle practices will need to be adjusted based on tree size and farm

equipment. Before a large canopy develops, tillage is possible around young trees but may damage peach tree roots. When an orchard is initially established, practices that utilize heat (flaming or steam) can be effective methods to terminate emerging weeds in alleys, but growers need to be mindful to not damage young trees (Abulridha et al. 2019; Fennimore et al. 2017). A plant-based mulch (i.e., straw, pine bark) that is 3–4 inches (7–10 cm) thick can be used to reduce weed growth, but it will degrade, may affect nutrient availability, and will need to be replaced yearly. A manufactured mulch (i.e., landscape fabric or plastic) will persist longer than a plant-based mulch but may affect water penetration and other abiotic conditions, such as soil and canopy temperature. After attempting preventative weed management practices, organic compliant chemical weed management options are available with variable efficacy depending on species, age of weed, and rate of application. OMRI-certified inputs can be found at www.omri.org, but all growers need to consult with their certification agency before application.

Irrigation and Fertilization

Peach trees require a variable amount of water throughout the season. During dormancy, irrigation will likely not be needed, but it will be needed during flowering and fruit growth. Tree growth, soil, and meteorological conditions will determine how much irrigation is required. For more information, review HS1316, *Irrigation Practices for Peaches in Florida*, at <https://edis.ifas.ufl.edu/hs1316>. Peach trees require additional fertilization for optimum growth and productivity (Table 2), and a summary of fertility sources allowed in organic systems can be found in HS720, *Introduction to Organic Crop Production* (<https://edis.ifas.ufl.edu/cv118>).

Peach tree nutrient status can be determined by collecting leaf plus petiole tissues and submitting them to a laboratory for analysis. Samples can be collected at any time during the growing season to confirm a suspected deficiency, but growers wishing to validate their nutrient management program and plan for spring fertility applications should collect leaf samples after harvest (typically June) to correct any deficiencies (Table 3) while the trees are still growing. Soil tests are typically conducted after harvest and fertilizer applications adjusted to maintain proper fertility levels for the remaining and next year. Often, established organic systems require less nitrogen-based inputs than conventional systems to achieve similar yields due to increased nutrient-cycling efficiency (Halberg 1995). However, in newly established orchards, additional nitrogen (N) may be required to offset the decreased nutrient-cycling efficiency.

Synchronizing N availability with crop demand is necessary, and growers will need to consider the applied product, application timing, temperature, and soil moisture in relation to N availability. Incubation studies that describe N release and plant availability for multiple organic-approved inputs have been conducted at soil temperatures similar to Florida summer (86°F or 30°C; Cassity-Duffey et al. 2020) and winter (73°F or 22.8°C; Lazicki et al. 2020), but additional studies are needed for locally available products. General observations from these studies show that most of the N is released from these products within 20 days and the N availability as a percentage of total N in the product over 100 days depended on material type: composted plant materials (~2%–4%), composted manure (~15%–30%), poultry litter (~20%–50%), and commercially blended fertilizers (~20%–80%). In a Florida study, researchers noted that compost with an 85% fertilizer efficiency, 2% N content, and a carbon:nitrogen ratio ≤ 25:1, applied at approximately 1.5 tons/acre, may satisfy the N requirement of a mature peach tree if applied in three applications (Litvany and Ozores-Hampton 2002). UF/IFAS N recommendations for conventional peach production are the only recommendations available at this time, and you are encouraged (and may be obligated, depending on your location in the state) to follow these recommendations. A recent fertigation study in Florida showed that excess applied nitrogen that does not leach through the soil is stored in the peach wood, including those branches that are removed in summer/postharvest pruning; therefore, the nitrogen is wasted because pruned branches are typically removed from the field (Rubio Ames et al. 2020). Notice nitrogen demand increases each year up to the fourth year (Table 2).

Integrated Pest and Pathogen Management

Insect and pathogen (Figure 4) management is one of the most challenging aspects of successful organic production. Growers employing the most effective organic compliant practices have claimed that over 50% of their crop had been lost under high temperature and humidity conditions that promote increased insect pest and pathogen activity. In decreasing order as represented from the bottom of the triangle to the top, organic integrated pest management relies on prevention, cultural management, physical management, biological control, and chemical applications as a last resort (Figure 5).

Figure 4. Photographs of hemipteran pests, orthopteran pests, and fruit/trunk injury caused by arthropod pests, fungal diseases, and mechanical means taken at a central Florida organic peach orchard in 2018 and 2019. Red arrows indicate the location of hemipteran mouthparts.

Credits: David Campbell, UF/IFAS

Figure 5. Integrated pest and disease management triangle with examples of organic-approved management practices. Fundamentals for action or consideration begin at the bottom (prevention) with chemical management practices as the last resort.

Cultural management, especially sanitation, is critical for insect and disease management. Diseased limbs and wounded/diseased fruit should be removed from the field to reduce fungal spore production and suitable habitats for insect pests. Producers may compost trimmings of diseased plant material according to the federal regulation (7 CFR § 205.203): “Composted plant and animal materials produced through a process that: i) Established an initial C:N ratio of between 25:1 and 40:1; and ii) Maintained a temperature between 131°F (55°C) and 170°F (76.7°C) for 3 days using an in-vessel or static aerated pile system; or iii) Maintained a temperature between 131°F and 170°F for 15 days using a windrow composting system, during which, the materials must be turned a minimum of five times.”

However, some causative organisms will survive, despite using the best available methods for composting. The NOP guidelines are appropriate for management of human disease-causing pathogens. Although specific types of plant pathogens will die at 122°F (50°C) (nematodes, oocytes, and water molds), other plant pathogens only die at 180°F (82.2°C) (Agrios 2005).

Growers are encouraged to remove alternative vegetative hosts, such as wild plum [*Prunus americana* (Marsh.)] from within 600 ft (183 meters) to reduce brown rot (*Monilinia fructicola*) inoculum and broad leaf weeds to reduce the number of stink bugs (Order: Hemipteran) (Blaauw et al. 2022). Additional cultural management activities include using drip or microsprinkler irrigation at the base of the tree to avoid wetting the leaves, which may increase fungal spore growth and distribution, and regularly sanitizing all pruning tools (eOrganic 2020).

Producers with small orchards may remove insect pests using a vacuum or by hand (remove the insect pests and place them in a bucket of soapy water). However, this procedure is labor-intensive and impractical on a large scale. Other physical management options include spraying horticultural oils (Figure 5, Table 4) to provide a physical barrier on the fruit, leaves, limbs, and trunk. Recently, researchers found that manually bagging individual peach fruit with paper bags impregnated with wax reduced fruit fly oviposition by 82% and scab-like lesions (small black circular dots) by 84% (Campbell et al. 2021). Bags also potentially delayed maturity, but the practice of installing and removing bags is labor-intensive and highly dependent on labor and whether there is a market for this fruit.

Baited traps can be used to attract known pests, but it is unknown whether that technique is economically feasible to reduce fruit insect injury. Biological control agents, such as QST-713 or CPA-8 strains of *Bacillus subtilis* have been shown to produce an antifungal lipoprotein that suppresses brown rot, can be sprayed on leaves throughout the season, and possibly can be combined with foliar micronutrient applications (if allowed according to the label and the grower’s certification agency). Biological agents compete with microbial and fungal pathogens for food and resources on the leaves or exude chemicals that slow or stop pathogen growth. The applications of beneficial nematodes, *Steinernema carpocapsae* and *Heterorhabditis bacteriophora*, have been used successfully against peachtree borer (*Synanthedon exitiosa*) larvae when applied directly to cracks in the bark or to frass on the plant.

Action thresholds for chemical control of pests are site-specific, and although it is the last resort, growers regularly use organic compliant chemicals to control pests and pathogens. The *Southeastern Peach, Nectarine, and Plum Management and Culture Guide* (Blaauw et al. 2022) lists organic compliant chemical controls (Table 4), but all growers need to consult with their certification agency before application. In addition to these chemicals, growers in central Florida have been observed to rotate the QST 713 strain of *Bacillus subtilis*, pyrethrins, and a combination of rosemary oil/geraniol/peppermint oil after action thresholds have been reached. The effectiveness of many plant-based essential oils have been reported as having broad-spectrum activity against many plant pathogens, including fungi, bacteria and even soft-bodied arthropod pests (Calo et al. 2015; Nazzaro et al. 2017). Research on the effectiveness of eight essential oils to reduce *Colletotrichum*, *Botryosphaeria*, *Fusarium*, and *Phytophthora* activity on tropical fruits was promising (Sarkhosh et al. 2017; Sarkhosh et al. 2018a; Sarkhosh et al. 2018b). In 2021, a research team led by Sarkhosh tested Thymeguard, an OMRI-listed formulation of 23% thyme oil, on four strains of peach brown rot (*Monilinia fructicola*) grown on amended media under lab conditions. Preliminary results included a significant reduction in spore germination of all four strains on the amended media. In February 2022, the research team started an experiment applying Thymeguard every 10–14 days on organically grown peach trees to evaluate the efficacy of the product not only on brown rot but also on other peach tree diseases. Preliminary results for the field experiment will be concluded in May 2022, and additional testing will be conducted before official guidance is published.

Results from competitive grants that were awarded to other peach-producing regions (Pennsylvania and California) have provided positive experimental findings for pest and disease injury prevention (OFRF 1994; SARE 2013). While the research was completed on USDA-certified organic farms, the outcomes may differ in Florida. In Pennsylvania, researchers report that perennials grown in hedgerows near peach orchards in Pennsylvania harbor beneficial insects, such as a syrphid fly. They report that ladybug beetles control green peach aphids, but syrphid fly larvae were not observed in aphid colonies. Praying mantid adults and eggs were found in peach trees, coinciding with the increase in stink bug populations. Kaolin clay was applied to prevent plum curculio injury in this study, but the researchers did not measure efficacy (SARE 2013). In other studies, kaolin clay combined with selected plant extracts (Gökçe et al. 2013) increased insect pest aversion and effectively reduced

oviposition in cotton (Showler 2002). Also, kaolin clay holds potential for controlling fruit flies, *Anastrepha* spp., in Florida.

In California, researchers reported that a mixture of Algrow kelp (3 lb or 1.36 kg), basalt rock dust milk (80 gal or 363.7 liters), and pink mucoid yeast (10 gal or 45.5 liters) sprayed on peach trees reduced brown rot. The researchers reported that 94% of the fruit did not have brown rot infection at harvest as compared to 58% for the untreated control. The Algrow kelp was a commercially available, cold-pressed, dry kelp product. The basalt rock dust milk was basalt rock dust mixed with 1 gal (153.7 fl oz; 4.6 liters) of a commercially available liquid kelp. The pink mucoid yeast was a cultured product with yeast that was scraped from peach leaves in the same orchard. Less effective treatments included hydrogen peroxide, compost tea (various), axomite clay and 1 gal (4.6 liters) liquid kelp, wine vinegar, raw apple cider vinegar, irrigation water with high algae content, and wettable sulfur (OFRF 1994). Producers using this approach in northern California have continued to update their materials to maintain compliance with the NOP, and an updated list of materials is available at eorganic.org in [Table 3 in the Woodleaf Farm Organic Systems Description](#) (Rosato et al. 2021). *As always, please obtain approvals from your certification agency before making any changes to your organic system plan.*

Harvest and Storage

The most practical ways to determine peach maturity are to observe the change in peel color (“ground color”) around the stem end from green to yellow/orange and to assess the firmness of the tip of the fruit (Brovelli et al. 1998). The red “blush” on the peel is formed in response to sunlight exposure and is not related to maturity. Peach fruit begin to ripen at the tip or blossom end and firmness should be assessed as the ground color begins to change. By grasping the fruit with the stem between the index and middle fingers, growers can easily assess the firmness by slightly pressing on the tip of the fruit with the thumb. Fruit to be marketed as “tree ripe” can be picked as soon as the tip begins to soften. During early ripening, the depressed tip will immediately resume the original shape, but if pressed too hard or assessed later in the season, the peel may break and/or the tip will remain depressed and vulnerable to fungal infection.

Peaches are climacteric, which means that when picked at the full mature stage, they can continue to ripen after harvest (unlike nonclimacteric fruit like citrus that can only ripen while on the tree). If harvested fruit are not cooled

immediately, the ripening process will occur rapidly. If the fruit will be packed the following day, they should be cooled within a couple of hours of harvest to 45°F to 50°F (7°C to 10°C) using forced-air cooling or hydrocooling. However, if packing will occur even later, the fruit should be cooled to near 32°F (0°C) for storage up to 1 to 3 months at that temperature with a relative humidity at 90% to 95%. Storage of peaches at 36°F to 45°F (2°C to 7°C) can favor development of a disorder called chilling injury or “internal breakdown,” which causes undesirable sensory perception characterized as lack of aroma, “woolly” or mealy, dry pulp texture, and reddish-brown flesh discoloration. Lower temperatures inhibit the development of chilling injury symptoms. Therefore, long-term storage should be below the 36°F to 45°F temperature range, and temporary storage should be at nonchilling temperatures above that range. The freezing point of peach fruit varies from 27°F to 30°F (-3°C to -1°C) depending on the concentration of sugars in the fruit—higher sugar content corresponds to lower freezing point (Gross et al. 2016).

Peach brown rot is a very common postharvest storage decay caused by the fungus *Monilinia fructicola*, which infects fruit in the orchard. In addition to the benefit of cooling in reducing postharvest decays, bagging young fruit in the field reduces pathogen infection so that the likelihood of fruit developing brown rot at harvest is reduced by 69% (Figure 6) (Campbell et al. 2021). Following bag removal at the time of harvest, after 7 days of storage, brown rot decreased by 32%. For more information about peach brown rot including pictures, visit the EDIS publication HS1357, *Peach Brown Rot* (<https://edis.ifas.ufl.edu/hs1357>).

Figure 6. Time-lapse photographs of brown rot progression of organically grown peaches grown with or without bags at harvest and after seven days of storage at 68°F (20°C) and 83% relative humidity. Credits: David Campbell, UF/IFAS

The populations of microbes that cause foodborne human illnesses and postharvest fruit decays can also be reduced with organic compliant sanitizers. Approved sanitizers include ozone (requires special equipment), peroxyacetic acid, acetic acid, hydrogen peroxide, and

low concentrations of chlorine (hypochlorite ion; bleach). Chlorine must be labelled specifically for sanitation (food grade) and can be purchased locally, but an extra rinse with potable water is required before shipping. Other products can be distinguished by an OMRI label (eOrganic 2020). Growers should be mindful of fruit and water temperatures during hydrocooling, which requires the use of sanitizer in the recirculated water to minimize cross-contamination of fruit. Fruit will absorb water (and sanitizer) during the cooling process if the fruit are immersed in water that is $\geq 10^{\circ}\text{F}$ (-12°C) cooler than the fruit. If the sanitizer, such as chlorine, requires an additional rinse before sale, then the fruit that absorbed sanitizer would no longer be processed according to organic standards and, hence, cannot be labeled as such. Shower-type hydrocoolers largely avoid this immersion-absorption issue.

Check with your certifying agent before applying fruit coatings to ensure the product is allowed for use. Packaging materials, including bags, bins, and shipping containers that contact the fruit must be new, or if reused or shared with a noncertified segment of your operation, must be thoroughly cleaned (and documented as such) before using in your organic system. Organic peaches must be kept separate from conventional produce during harvest and collection operations as well as during cooling, packing, storage, transportation, and display shelves in stores to prevent contact with surfaces that may have residues of prohibited products. This is referred to as comingling.

For more information on postharvest handling of specialty crops, please review the UF/IFAS EDIS publication, HS1270, *Postharvest Storage, Packing and Handling of Specialty Crops: A Guide for Florida Small Farm Producers* at <https://edis.ifas.ufl.edu/hs1270> or the University of California Postharvest Center’s *Management for Organic Fruit and Vegetable Crops* at http://postharvest.ucdavis.edu/Online_Extension_to_Educate_Small_Farms/Postharvest_Management_for_Organic_Fruit_and_Vegetable_Crops/.

Table 1. Perennial planting stock, growing media/location, and associated waiting period between establishment and time required before selling as USDA-certified organic.

Perennial Planting Stock	Growing Medium/Location	Waiting Period*
Organically grown	Planted incertified organic system land or pots. Produced with compliant inputs, including mulch, compost, and pest management products.	None. Fruit may be marketed with the USDA-Organic label.
Conventionally grown	Planted in certified organic system land or pots.	12 months (7 C.F.R. § 205.204)
Organic or conventionally grown	Planted in noncertified organic system land or pots.	36 months

* Note: Waiting period duration is contingent upon meeting all organic system certification requirements and system certification can only be granted by the organic certification agency.

Table 2. Annual fertilizer recommendations for peach orchards in Florida.

Year	Sandy Soils (Central Florida) ¹			Loamy Soils (North and West Florida) ²		
	N ⁴	P ₂ O ₅ ^{3,4}	K ₂ O ^{3,4}	N	P ₂ O ₅	K ₂ O
	----- lb/acre -----			----- lb/acre -----		
One	11.3	3.8	7.8	12.8	8.6	8.6
Two	25.9–38.9	8.6–13.0	17.9–25.9	17.3–25.9	17.3–25.9	17.3–25.9
	80.0	26.7	53.3	80.0	80.0	80.0
Four +	99.0	33.0	66.0	99.0	99.0	99.0

Modified from Ferguson et al. (2007)
¹Base fertilizer used was 12-4-8 (N-P-K)
²Base fertilizer used was 8-8-8 (N-P-K)
³N = nitrogen; P = phosphorus; K = potassium
⁴P × 2.291 = P₂O₅; K × 1.205 = K₂O

Table 3. Peach leaf plus petiole deficiency and sufficiency ranges for selected nutrients.

	N	P	K	Ca	Mg	S	Zn	B	Fe	Mn	Cu
	----- % -----						----- ppm -----				
Deficiency threshold	2.2–2.4	0.09–0.12	0.8–1.0	1.0	0.1–0.3	0.09	10–20	15–30	-	20	3
Sufficiency range	2.6–3.5	0.14–0.40	2.0–3.0	1.5–3.0	0.3–0.8	0.14–0.40	20–50	30–70	80–250	40–200	5–16

Modified from Johnson (2008).
 Data presented were not collected from low-chill peach.

Table 4. Pests and management options for organic peach production systems in Florida. This table is a summary of compliant approaches only, and it does not replace the product label. Verify compliance and receive approval for use from your certification agency before using any products in your transitioning or certified system. For the most current recommendations and label instructions, please visit the *Southeastern Peach, Nectarine, and Plum Pest Management and Culture Guide*. Please note this guide contains prohibited and approved products that have been tested and determined to be effective in the Southeast. See <https://hos.ifas.ufl.edu/stonefruit/production/>. Pesticide experts include (1) Insecticides and Miticides: Oscar E. Liburd, UF/IFAS Entomology and Nematology Department; (2) Fungicides and Bactericides: Phil Harmon, UF/IFAS Plant Pathology Department; and (3) Organic Compliance: Danielle Treadwell, UF/IFAS Horticultural Sciences Department.

Pest(s)	Damage	Cultural Practices and Remarks	Material	Spray Timing, REI*, and PHI*
ARTHROPOD PESTS				
European red mite [<i>Panonychus ulmi</i>] ¹	Feed on foliage, cause leaf bronzing and speckling, reduce fruit growth and cause preharvest fruit drop.	European red mites are considered secondary pests that are typically managed with predatory mites, ladybird beetles, and the six-spotted thrips. ⁴	<i>dormant horticultural (superior) oil</i>	Spray from dormancy to 5% bud swell REI = 12 hours PHI = prebloom only
Lesser peachtree borer [<i>Synanthedon exitiosa</i> (Grote and Robinson)] ¹	Females oviposit on upper trunk/scaffold branches. Larvae feed in galleries (tunnels bored in the wood), weakening the tree, and expose the tree to other pathogens.	Destruction of alternate hosts is not a viable option because the adults are strong flyers. Healthy and appropriately fertilized trees are better at sustaining damage. Pupation occurs underground within 2 inches of the trunk, but tillage to destroy pupae may damage the root system. ⁴ The use of beneficial nematodes as a curative application has shown promise when combined with an anti-desiccant to keep the tree wounds moist long enough for the nematodes to find the larvae inside the tree.	<i>dormant horticultural (superior) oil</i>	Spray from 1% to 5% bud swell REI = 12 hours PHI = prebloom only
Scales, White peach [<i>Pseudaulacaspis pentagona</i> (Targioni)] and Scale, San Jose [<i>Quadraspidiotus perniciosus</i> (Comstock)] ¹	Feeding and toxin injection will weaken and potentially kill limbs.	Management of scale is difficult because the scales protect themselves with a hard, waxy armor. Predators such as ladybird beetles, common lacewings, and gall midges provide some protection. Chemical applications are directed at the larval or crawler stages. ⁴	<i>dormant horticultural (superior) oil</i>	Spray from dormancy to 5% bud swell REI = 12 hours PHI = prebloom only
Flower thrips [<i>Frankliniella tritici</i> (Fitch)] ¹	Rasping injury on fruit.	Minute pirate bugs are the most effective predator. Spinosad is a short residual material. Spray in the late afternoon to protect bees and is safe to bees after dry.	<i>spinosad</i> (MOA 5) SpinTor 2SC or Entrust 80W	Spray from pink to 5% bloom REI = 4 hours PHI = 14 days

Pest(s)	Damage	Cultural Practices and Remarks	Material	Spray Timing, REI*, and PHI*
FUNGAL AND MICROBIAL PESTS				
Bacterial spot (<i>Xanthomonas arboricola</i>) ¹	Shot hole in leaf, premature defoliation, fruit lesions. 'Florida Prince' and 'Tropic Beauty' are more susceptible to bacterial spot than newer varieties.	Securing healthy rootstock absent of the pathogen is critical during orchard establishment. Afterwards, removal of infected plant parts will reduce the inoculum and other chemical applications may be necessary. Materials may only be used if the requirements of § 205.206(e) are met, which requires the use of preventative, mechanical, physical, and other pest, weed, and disease management practices. Copper (Cu) is protective and must be present prior to the onset of conditions that lead to infection. Even coverage is important. Must be used in a manner that minimizes copper accumulation in the soil. ⁵	basic copper sulfate Cuprofix Ultra 40 Dispers (40% MCE)	Spray from dormancy to shuck split. Do not apply after split shuck. REI = 48 hours PHI = Prebloom ⁶
			cuprous oxide Nordox 75WG (75% MCE)	Spray from dormancy to 10% shuck off. REI = 12 hours PHI = 3 weeks
				Spray from petal fall to 1% shuck split. REI = 24 hours PHI = 3 weeks
			copper hydroxide Kocide 2000 (35% MCE) or Kocide 3000 (30% MCE)	Spray from dormancy to 5% bud swell. REI = 12 hours PHI = 3 weeks
				Spray from pink through summer. REI = 48 hours PHI = 3 weeks
			copper oxychloride plus copper hydroxide Badge SC (20% MCE)	Spray from dormancy to 10 days after shuck split. REI = 48 hours PHI = 3 weeks
Brown rot (<i>Monilinia fructicola</i>) ^{1,3}	Fungal lesions on fruit	Removal of infected plant parts will reduce the inoculum in the orchard. Observe instructions from the manufacturer and consult with your local Extension agent. Levels of free chlorine in discharged water must not exceed safe drinking levels. Do not apply when weather conditions favor drift or runoff. May require retreatment.	Calcium hypochlorite CCH HTH or Sodium hypochlorite AgClor 310	Postharvest fruit handling

Pest(s)	Damage	Cultural Practices and Remarks	Material	Spray Timing, REI*, and PHI*
			<i>Bacillus subtilis</i> strain QST 713 Serenade Max	Spray during season or after harvest. REI = 4 hours PHI = 0 hours
Leaf curl (<i>Taphrina deformans</i>) ¹	Distorted red foliage, fruit drop	Secure healthy trees to ensure successful orchard establishment. Remove infected plant parts to reduce inoculum and conduct other chemical applications as necessary. ⁵	See notes for copper formulations for bacterial spot.	Spray from dormancy to 5% bud swell. Typically treated when treating for bacterial spot, and rarely treated on its own.
Peach scab (<i>Cladosporium carpophilum</i>) ¹	Leaf, stem, and fruit lesions	Secure healthy trees to ensure successful orchard establishment. Remove infected plant parts to reduce inoculum and conduct other chemical applications as necessary. Coverage of exposed peach tissue is important for disease management.	sulfur (MOA M2) Captan 50W or 80WDG or Captec 4L	Spray from petal fall to summer. REI = 24 hours PHI = 0 days
Peach rust (<i>Transchelia</i> spp.) ²	Leaf lesions	Peach rust requires an alternate host to complete a lifecycle. In California, an alternate host is a wild poppy (<i>Anemone cornaria</i>). Alternate hosts have not been confirmed in Florida, but two species of <i>Anemone</i> are present along the nature coast and northern peninsula. Removal of alternate hosts will help, but the spores are transmitted long distances by air and moved around in the orchard by water. To avoid leaf damage do not apply sulfur when temperatures >90°F (>32°C).	sulfur (MOA M2) (MOA M2) Captan 50W or 80WDG or Captec 4L	Spray in spring. Use multiple applications if disease was severe in the previous year. REI = 24 hours PHI = 0 days

1. Adapted from *Southeastern Peach, Nectarine, and Plum Management and Culture Guide* (Blaauw et al. 2022).

2. Adapted from *Peach Rust* (Mancero-Castillo et al. 2018).

3. Adapted from "Biological Control of Peach Brown Rot (*Monilinia* spp.) by *Bacillus subtilis* CPA-8 Is Based on Production of Fengycin-Like Lipopeptides" (Yáñez-Mendizábal et al. 2012).

4. Consult with certification agency because some oils contain prohibited substances. Spraying during the daytime hours can cause foliar damage.

5. Phytotoxicity concerns are present and rates should be appropriate for crop development and rainfall patterns. Applications during late dormant season for areas with a history of infection are recommended to reduce bacterial populations before bloom.

6. Adapted from *Tree Fruit Production Guide: Reentry and Preharvest Intervals* (PennState Extension 2022).

*Abbreviations used: Restricted-Entry Interval (REI), Preharvest Interval (PHI), Metallic Copper Equivalent (MCE).
